Abstract.

Integral transform approaches are numerous in many fields of physics, but in most cases limited to the use of the Laplace kernel. However, it is well known that the inversion of the Laplace transform is very problematic, so that the function related to the physical observable is in most cases unaccessible. The great advantage of kernels of bell-shaped form has been demonstrated in few-body nuclear systems. In fact the use of the Lorentz kernel has allowed to overcome the stumbling block of the ab initio description of reactions to the full continuum of systems of more than three particles. The problem of finding kernels of similar form, applicable to many-body problems deserves particular attention. If this search were successful the integral transform approach might represent the only viable ab initio access to many observables that are not calculable directly.

1. Introduction

Integral transform approaches to physical problems are common to many fields in physics, e.g. nuclear physics, condensed matter physics and quantum chromo-dynamics. The motivation to use such approaches originates from the fact that, while one is often unable to evaluate a physical quantity of interest $\mathcal{X}$, directly, one can calculate a few of its integral properties. Particularly interesting are integral transforms. They can give information on $\mathcal{X}$. However, a sufficiently detailed reconstruction of $\mathcal{X}$ (inversion of the transform) is sometimes a formidable task or even impossible. One of the reasons is that in many cases the integral property known to be accessible by a numerical technique is the Laplace transform ($\mathcal{LT}$). This occurs in the numerous physical processes that are described by diffusion equations. Problems involving $\mathcal{LT}$s also arise in computing statistical functions, which is very common in many fields.

From the Mellin's inverse formula (Bromwich integral) for the inverse Laplace transform [1], one sees that it is necessary that the $\mathcal{LT}$ is computable in the complex half-plane of convergence. In this case $\mathcal{X}$ can be computed by evaluation of a complex

path integral, which can be a formidable task. However, in the common situation when the Laplace transform is computable (or measurable) on the real and positive axis only, the problem is extremely *ill-posed*. This case is much more complicated because of the absence of an exact inversion formula. In addition, as it will be explained below, one can say that among *ill-posed* problems, the inversion of the $\mathcal{LT}$ is one of the worst. There are some more or less efficient numerical methods available for computing the inverse transform [2, 3], however, in general when the input is numerically noisy and incomplete it may be impossible to obtain a stable result [4].

In the last fifteen years it has been shown that an integral transform approach with a *bell-shaped* kernel, namely the Lorentzian function [5], helps in solving a longstanding problem in few-body physics, i.e. the calculation of reactions involving states in the far continuum of four- ([6]-[10]) and even six- [11] and seven- [12] body systems (for a review see [13]). The scope of this contribution is to (i) clarify why the Lorentzian function is a *good* kernel (section 1), (ii) discuss the limits of this approach (section 2) (iii) define the **open problems** (section 3) and (iv) suggest possible directions to explore for finding solutions (section 4).

2. Why is the Lorentzian function is a *good* kernel ?

To illustrate what is the intrinsic origin of the difficulties in inverting transforms with the Laplace kernel or, similarly, with the Stieltjes kernel [14, 15], consider figure 1. The upper panel shows two functions $r_1(E)$ and $r_2(E)$, while in the middle panel their $\mathcal{LT}$s are plotted, i.e.

$$\Phi(\sigma) = \int K(\sigma, E)\, r(E)\, dE\,, \tag{2.1}$$

with $K(\sigma, E) = e^{-\sigma E}$. As one can see the curves in figure 1(a) do not resemble the curves in figure 1(b). The functios $r_i(E)$ exhibit a peak, while the $\mathcal{LT}$s are monotonically decreasing. Moreover, one sees that though $r_1(E)$ and $r_2(E)$ are rather different they lead to very similar $\mathcal{LT}$s. Considering that both transforms could lie within the error of a numerical calculation one understands that it is impossible by inversion to distinguish between the curves in 1(a). The reason is that the Laplace kernel has spread the information over a very large domain. As shown in 1(c) the situation is different for the Lorentz integral transform (LIT), where the kernel of the transform is the Lorentzian function

$$K(\sigma_R, \sigma_I, E) = \frac{1}{(E - \sigma_R)^2 + \sigma_I^2}\,. \tag{2.2}$$

The form of the functions in 1(c) is preserved and the relative difference between the LITs, is of the same order as it is for the functions in 1(a).

We do not intend to discuss here the problem of the inversion of integral transforms, which are known in mathematics under the name of *ill-posed problems*. An extended literature exists about this topic (see e.g. [16]). We only want to mention that, contrary to what the unfortunate name might suggest, they can be solved using regularization

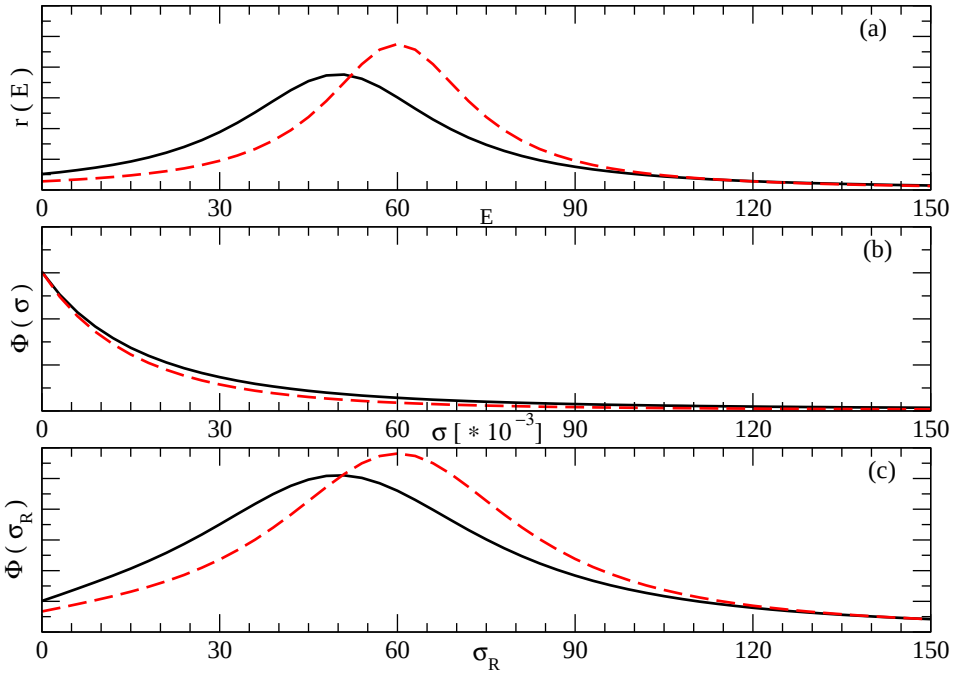

Figure 1. (a): The functions r_1 and r_2, (b): their Laplace transforms, (c) their Lorentz transforms with $\sigma_I = 10$.

methods. Such methods are very efficient when the kernel is bell shaped with a controllable width. A clarifying discussion about this point can be found in [17].

In relation to what has been said above, one could think that the perfect kernel is a $\delta-$function, i.e. $K(\sigma_R, E) = \delta(\sigma_R - E)$. In fact in this case the function and its transform would coincide. While this clearly does not help, the Lorentzian function, which up to normalization turns to the δ-function at $\sigma_I \to 0$, has the necessary characteristics, as have the Gaussian functions or other bell-shaped kernels.

However, it is clear that the other *conditio sine qua non* for applying an integral transform approach to physical problems is that the transform is calculable in practice. In [5] it was suggested that the Lorentzian kernel might satisfy both requisites when applied to a specially difficult and unsolved problem, i.e. the *exact* (ab initio) calculation of perturbation induced reactions to states in the continuum (scattering states) of a many-body system. In the following we will shortly summarize why this is the case. More extensive information can be found in [13], where the successful applications of what is now known as the Lorentz integral transform method have been reviewed and the procedure to apply it also to non-perturbative reactions has been outlined.

2.1. Short summary of the LIT method

Very often physical quantities of interest have (or may be reformulated to have) the following structure

$$r(E) = \sum\!\!\!\!\!\!\int d\gamma \langle Q|\Psi_\gamma\rangle\langle\Psi_\gamma|Q'\rangle\delta(E_\gamma - E), \tag{2.3}$$

where the integration and summation go over all the complete and orthonormal set of eigenstates $|\Psi_\gamma\rangle$ of an hamiltonian $\hat{H}$ and the norms $\langle Q|Q\rangle$ and $\langle Q'|Q'\rangle$ are finite.

When the energy E and the number of particles in a system increases the direct calculation of the quantity $r(E)$ becomes prohibitive. The difficulty is related to the fact that in these cases a great number of continuum spectrum states $|\Psi_\gamma\rangle$ contribute to $r(E)$ and the structure of these states is very complicated.

In order to overcome the problem one can consider instead an integral transform with a smooth kernel $K(\sigma, E)$. This yields

$$\begin{aligned}\Phi(\sigma) &= \sum\!\!\!\!\!\!\int d\gamma \langle Q|\Psi_\gamma\rangle K(\sigma, E_\gamma)\langle\Psi_\gamma|Q'\rangle \\ &= \sum\!\!\!\!\!\!\int d\gamma \langle Q|\hat{K}(\sigma,\hat{H})|\Psi_\gamma\rangle\langle\Psi_\gamma|Q'\rangle.\end{aligned} \tag{2.4}$$

Using the closure property one obtains

$$\Phi(\sigma) = \langle Q|\hat{K}(\sigma,\hat{H})|Q'\rangle. \tag{2.5}$$

The right–hand side of (2.5) requires only the knowledge of the finite norm functions $|Q\rangle$ and $|Q'\rangle$ and avoids completely the full knowledge of the spectrum of $\hat{H}$. (It is clear that what is presented here can be considered as a generalization of the sum rule, namely the *moment method*).

Choosing for $K(\sigma, E)$ the Lorentzian function

$$K(\sigma, E) = \frac{1}{(E - E_0 - \sigma_R)^2 + \sigma_I^2}\,. \tag{2.6}$$

where

$$\sigma = E_0 + \sigma_R + i\sigma_I \qquad \sigma_I \neq 0, \tag{2.7}$$

and E_0 is the ground–state energy, one has

$$\begin{aligned}L(\sigma_R, \sigma_I) &= \langle Q|\frac{1}{(\hat{H} - E_0 - \sigma_R + i\sigma_I)}\frac{1}{(\hat{H} - E_0 - \sigma_R - i\sigma_I)}|Q'\rangle \\ &\equiv \langle\tilde{\Psi}|\tilde{\Psi}'\rangle\,,\end{aligned} \tag{2.8}$$

where the 'LIT functions' $\tilde{\Psi}$ and $\tilde{\Psi}'$ are solutions to the inhomogeneous equations

$$\left(\hat{H} - E_0 - \sigma_R - i\sigma_I\right)|\tilde{\Psi}\rangle = |Q\rangle\,, \tag{2.9}$$

$$\left(\hat{H} - E_0 - \sigma_R - i\sigma_I\right)|\tilde{\Psi}'\rangle = |Q'\rangle\,. \tag{2.10}$$

Let us suppose that $|Q\rangle = |Q'\rangle$). In this case $L(\sigma)$ equals to $\langle\tilde{\Psi}|\tilde{\Psi}\rangle$ ($\langle\tilde{\Psi}'|\tilde{\Psi}'\rangle$). Since for $\sigma_I \neq 0$ the integral in (2.1) does exist, the norm of $|\tilde{\Psi}\rangle$ ($|\tilde{\Psi}'\rangle$) is finite. This implies

that $|\tilde{\Psi}\rangle$ and $|\tilde{\Psi}'\rangle$ are *localized* functions. This means that in contrast to continuum spectrum problems, in order to construct a solution, it is not necessary here to reproduce a complicated large distance asymptotic behaviour in the coordinate representation or singularity structure in the momentum representation. This is a very substantial simplification.

3. What are the present limits of LIT applications ?

The LIT method has been successfully applied to quite a few physical problems. They regard electroweak reactions with **few-body** systems. An extension to **many body** systems, however, encounters at present some limits. They become clear in the following where we describe how one calculates the LIT $L(\sigma_R, \sigma_I)$ of equation (2.8)..

Most of the LIT applications have been solved by using complete many-body basis and expanding $|\tilde{\Psi}\rangle$ and $|\tilde{\Psi}'\rangle$ over N localized states. A convenient choice is to use N linear combinations of states that diagonalize the hamiltonian matrix. We denote these combinations $|\varphi_\nu^N\rangle$ and the eigenvalues ϵ_ν^N. The index N is to remind that they both depend on N. If the continuum starts at $E = E_{th}$ then at sufficiently high N the states $|\varphi_N\rangle$ having $\epsilon_\nu^N < E_{th}$ will represent approximately the bound states. The other states will gradually fill in the continuum as N increases. The expansions of our localized LIT functions read as

$$|\tilde{\Psi}\rangle = \sum_\nu^N \frac{\langle\varphi_\nu^N|Q\rangle}{\epsilon_\nu^N - E_0 - \sigma_R - i\sigma_I}|\varphi_\nu^N\rangle\,, \tag{3.1}$$

$$|\tilde{\Psi}'\rangle = \sum_\nu \frac{\langle\varphi_\nu^N|Q'\rangle}{\epsilon_\nu^N - E_0 - \sigma_R - i\sigma_I}|\varphi_\nu^N\rangle\,. \tag{3.2}$$

Substituting (3.1) and (3.2) into (2.8) yields the following expression for the LIT,

$$L(\sigma_R, \sigma_I) = \sum_\nu \frac{\langle Q|\varphi_\nu^N\rangle\langle\varphi_\nu^N|Q'\rangle}{(\epsilon_\nu^N - E_0 - \sigma_R)^2 + \sigma_I^2}\,, \tag{3.3}$$

and for the common case $|Q'\rangle = |Q\rangle$

$$L(\sigma_R, \sigma_I) = \sum_\nu \frac{|\langle\varphi_\nu^N|Q\rangle|^2}{(\epsilon_\nu^N - E_0 - \sigma_R)^2 + \sigma_I^2}\,. \tag{3.4}$$

From (3.3) and (3.5) it is clear that in this way $L(\sigma_R, \sigma_I)$ becomes a sum of Lorentzians. The spacing between the corresponding eigenvalues with $\epsilon_\nu^N > E_{th}$ depends on N and in a given energy interval the density of these eigenvalues increases with N. (Since the extension of the basis states grows with N, this resembles the increase of the density of states in a box, when its size increases). For the reliability of the inversion one needs to reach the regime where one has a sufficient number of levels ϵ_ν^N in a $[\sigma_R - \sigma_I, \sigma_R + \sigma_I]$ interval.

In a similar way one can obtain other integral transforms with bell shaped kernels e.g. the Gauss integral transform (GIT) $K(\sigma_R, \sigma_I, E) = e^{-(E-\sigma_R)^2/\sigma_I^2}$:

$$G(\sigma_R, \sigma_I) = \sum_\nu |\langle \varphi_\nu^N | Q \rangle|^2 e^{-(\epsilon_\nu^N - \sigma_R)^2/\sigma_I^2} \ . \tag{3.5}$$

It is clear that for a many-body system this is a formidable task, because of the larger and larger degeneracy of states with increasing N and the little chance that out of the many states a significant number is found within the σ_I extension. In this resides the limit of the LIT method if one wants to extend it to many-body systems.

A more efficient procedure can be applied using the Lanczos approach. This consists in rewriting $L(\sigma_R, \sigma_I)$ as

$$L(\sigma) = -\frac{1}{\sigma_I} \mathrm{Im} \left\{ \langle Q | \frac{1}{\sigma_R + i\sigma_I + E_0 - \hat{H}} | Q' \rangle \right\} \ . \tag{3.6}$$

and then as a continuous fraction in function of the Lanczos coefficients a_i and b_i

$$L(\sigma) = -\frac{1}{\sigma_I} \mathrm{Im} \left\{ \frac{\langle Q | Q' \rangle}{z - a_0 - \frac{b_1^2}{z - a_1 - \frac{b_2^2}{z - a_2 - b_3^2 \cdots}}} \right\} \ . \tag{3.7}$$

This has the big advantage that one has not to diagonalize or invert the hamiltonian matrix, however the problem of extending the method to many-body systems remains similar to the previous case.

Important remarks:

- We would like to emphasize that, contrary to discretization approaches to the continuum, here the use of a discrete basis is perfectly legitimate, because of the bound state like boundary conditions of $|\tilde{\Psi}\rangle(|\tilde{\Psi}'\rangle)$. The continuum spectrum is recovered with a controlled resolution by the regularization when inverting the transform.
- One can notice that equation (3.5) corresponds to the following common procedure. This consists in diagonalizing the hamiltonian on a discrete basis and then folding the $|\langle \varphi_\nu^N | Q \rangle|^2$ with a Lorentzian function (or a Gaussian function), in order to simulate the "experimental window". However, as equation (3.5) clearly states, this **does not** represent $r(E)$ itself, but its LIT (GIT), that has to be inverted (see [13], figure 5 and relative discussion).
- Considering our discussion one realizes that, within the eigenvalue approach, the difficulties in generalizing the integral transform method to many body systems do not lie in the kernels, that may be chosen conveniently, but in handling very large basis.

4. Open problems

The problem of calculating exactly (ab initio) reactions to continuum states (scattering states) of many-body systems is one of the oldest open problems in Quantum Mechanics.

Many important steps have been made in the last years towards a solution, thanks to the integral transform method. However, much has still to be done and we summarize the main problems in the following.

- **Application of the LIT method to few-body non-perturbative processes** (hadron scattering). The LIT method has been applied successfully only to inclusive and exclusive perturbation induced processes. The formalism for applications to non perturbative processes already exists. One can find it briefly discussed in section 2.3 of [13]. It is essentially a reformulation with the Lorentz kernel of the original idea in [14] with the Stieltjes kernel.
- **Spectra presenting narrow resonances.** From (2.9) and (2.10) it is clear that the smaller the width σ_I the more slowly the LIT functions $\tilde{\Psi}$ approach zero at large distances, making it very hard to find accurate transforms [18]. In particular using expansions of $|\tilde{\Psi}\rangle$ over basis states one has to make sure that a sufficient number of $|\phi_\nu^N\rangle$ states have energies ϵ_ν^N in the resonance region Therefore very narrow resonances can be hardly resolved.
- **Integral transforms and many-body methods.** In section 3 it has been explained that for an extension of the LIT method to a larger number of particles one has to be able to handle very large basis. Investigating the use of the Coupled Cluster method to calculate the LIT is one of the interesting directions [19]. In alternative one could search for other kernels, that allow the calculation of the transform by some other methods. Due to the large use of MC approaches, not only in nuclear physics, but also in many other fields, from condensed matter to QCD, it would be very interesting to explore the applicability of Monte Carlo (MC) techniques to integral transforms with kernels other than the Laplace one. In the following section we suggest possible investigations along this line.

5. New directions to explore

As discussed in section 2 a good kernel has to be bell-shaped and has to generate a transform that can be calculated. The Laplace kernel leads to transforms of the kind

$$\Phi(\tau) = \langle Q | e^{[-(\hat{H}-E_0)\tau]} | Q' \rangle. \tag{5.1}$$

that are usually calculated by MC techniques (evolution in imaginary time). However, the kernel does not have the desired form. One difference between the Laplace and the Lorentz kernel is that the former is a function of one parameter (besides the integration variable), while the latter is a function of two parameters that have a specific function: one allows to regulate the width of the bell, the other, is connected to its maximum and allows *to scan* the function of interest over its domain. Therefore one should think of other two or more parameter kernels that are such combinations of exponentials to generate bell shaped kernels. One of them could be e.g. [20]

$$K(\sigma, \tau_1, \tau_2, E) = \Theta(E-\sigma)\left[e^{[-(E-\sigma)\,\tau_1]} - e^{[-(E-\sigma)\,\tau_2]}\right] \quad \tau_2 > \tau_1 > 0\,. \tag{5.2}$$

This is a bell shaped function that, with suitable choices of the parameters, allows to vary at wish both the width and the centroid. The Heaviside step function Θ ensures both that the exponents remain negative and that $K(\sigma, \tau_1, \tau_2, E)$ is positive definite. What is to investigate is whether a MC algorithm could be deviced to calculate

$$\Phi(\sigma, \tau_1, \tau_2,) = \langle Q|\Theta(\hat{H} - \sigma) \left[e^{[-(\hat{H}-\sigma)\,\tau_1]} - e^{[-(\hat{H}-\sigma)\,\tau_2]} \right] |Q'\rangle \,, \tag{5.3}$$

via imaginary time evolution as (5.1). Alternatively one can think of another representation of the δ-function, i.e.

$$K(\sigma, \tau, E) = \tau e^{-|(E-\sigma)|\,\tau} \tag{5.4}$$

where again τ and σ allow to change width and centroid of the kernel, respectively. The presence of the absolute value in the exponent again requires to deal with operators that contain the Θ operator. This might represent a problem.

Given the large number of physical problems in many different fields, that are connected to Laplace transforms, an effort to investigate the use of kernels like those proposed here, if successful, could open the way to many very interesting developments.
